

Abstract

**A Clinical Study of Free Vascularized Osteocutaneous
Fibular Transplantation in Infected Nonunion of Tibia**

February 1995 to September 1999, authors have experienced seven cases of infected nonunion of tibial fractures with associated soft tissue injury and skin defect, and have accomplished union in all cases by free vascularized fibular graft.

All grafts healed with no radiographic evidence of bone necrosis or resorption and have been able to treat large bony defect and skin defect simultaneously.

In this study, five cases of vascularized free fibular osteocutaneous flap transfer and two cases of free fibular graft are reported.

All of seven cases were infected nonunion of tibia.

The results were obtained as follows

- 1) The mean duration of the radiologic bone union was average 5.3months.
- 2) Grafted fibular has been hypertrophied, average 10.6 months.
- 3) In five cases of preservation of posterior cortex of tibia, bony union and hypertrophy of grafted bone were earlier than that two cases of complete segmental resection of tibia.
- 4) In two cases which only free vascularized fibular graft were performed because achievement of cutaneous flap was failed, authors found that soft tissue defect was filled with granulation tissue and split-thickness skin graft was possible over the granulation tissue after 3 weeks post-operatively.
