

An Unusual Occurrence of Epidermoid Cyst in the Inner Mucosa of the Upper Lip: A Case Report

Jihye Lee, Namki Choi, Seonmi Kim

Department of Pediatric Dentistry, School of Dentistry, Chonnam National University

Abstract

Epidermoid cysts are rare benign lesions in the oral cavity that may be either congenital or acquired. The cysts are usually slow-growing and asymptomatic until becoming secondarily infected or large enough to interfere with mastication and speech. Consequently, diagnosis is often delayed. The condition is also uncommon in newborns and infants. Most of the lesions occur in the floor of the mouth and rarely in the upper lip. This report describes the case of a 29-month-old girl with a palpable mass in the inner mucosa of the upper lip. The lesion was surgically enucleated using an intraoral approach and histopathologically diagnosed as epidermoid cyst.

Key words : Epidermoid cyst, Upper lip, Surgical enucleation

I. Introduction

Epidermoid cysts are common benign skin lesions that consist of epithelial-lined cavities, which are filled with viscous or semisolid epithelial degradation substances[1]. Such cysts can develop anywhere in the body. The incidence in the head and neck region ranges from 1.6 - 6.9%. Oral forms account for less than 0.01%[2]. The floor of the mouth is the most commonly involved site in the oral cavity[3]. Rare cases have been reported in the tongue, buccal mucosa, parotid gland, and lips[2,4].

Epidermoid cysts are usually benign, slow-growing, and painless. Most of the lesions are asymptomatic. As the lesions grow beyond, some symptoms such as difficulty in breathing and swallowing can appear[3]. These masses generally occur

in young adults, with pediatric presentation being less common[2].

In this case report, an epidermoid cyst located in the inner mucosa of the upper lip of a pediatric patient was detected and surgically treated. As reported in oral and maxillofacial surgery literature, such epidermoid cysts are not frequently diagnosed by pediatric dentists. Therefore, this is a rare case report of an epidermoid cyst in the upper lip from a pediatric dentistry department.

II. Case Report

A 29-month-old girl visited the Department of Pediatric Dentistry, Chonnam National University Dental Hospital, with a mass in the inner mucosa of the upper lip near the labial fren-

ulum. The lesion was first detected at an infant oral examination 2 weeks earlier. There was no history of previous surgery or trauma associated with the site of the lesion.

Intraoral examination revealed a well-demarcated, solitary swelling in the inner mucosa of the upper lip measuring 12.0 X 12.0 mm in its greatest dimensions. The overlying mucosa was normal in color and texture without any signs of inflammation (Fig. 1). The swelling was firm, non-tender, movable, smooth and not associated with discharge on palpation. On physical examination, no other swelling was noted elsewhere in the body. There was no associated lymphadenopathy.

Also, no unusual findings were detected on periapical radiographs (Fig. 2). Additional imaging techniques such as computed tomography (CT) or magnetic resonance imaging (MRI) were not performed as the patient was young, and the parents

refused to consent. Based on the clinical examination, a provisional diagnosis of lipoma or fibroma was made.

An excisional biopsy under oral sedation was planned due to the patient's cooperation. Under local anesthesia, a careful dissection was performed to enucleate the cyst (Fig. 3A). Underlying the inner mucosa of the upper lip, it was a well-encapsulated mass with yellow lesions measuring 12.0 X 12.0 X 18.0 mm. It could be separated from the surrounding tissues. Yellowish material was also present inside the capsule (Fig. 3B). The specimen was sent for histopathological examination. The area was then irrigated and primary closure was followed.

Histopathological examination showed a cystic cavity lined with stratified squamous epithelium and filled with lamellated keratin (Fig. 4). No skin appendages were identified. Histological analysis confirmed the diagnosis of epidermoid cyst.

Fig. 2. Periapical radiography shows normal characteristics of the structures.

Fig. 3. (A) Enucleation of the cyst intraorally. (B) Excised specimen measured 12.0 × 12.0 × 18.0 mm in size.

Fig. 4. Histopathological section showing a cyst lined by keratinized squamous epithelium, cavity filled with lamellated keratin.

Fig. 5. Postoperative intraoral view.

The patient was followed-up for 6 months, with no signs of recurrence. There were no scars or adhesions in the labial frenulum (Fig. 5). The movement of the lip was normal, implying that the function of the orbicularis oris muscle was not impaired.

III. Discussion

Histologically, dermoid cysts have been classified into epidermoid, dermoid, and teratoid cysts. Epidermoid cysts are lined with epithelium and derived from epidermal and con-

nective tissue. Dermoid cysts have cavities lined with a similar epithelium and containing structures such as hair follicles, sebaceous and sweat glands in the underlying connective tissue. Teratoid cysts have cavities lined by epithelium and containing derivatives of the endoderm and mesoderm, such as muscle, intestinal mucosa, respiratory mucosa, bone, blood vessels, and appendages. Overall, epidermoid cysts are the most frequently found type[4,5]

The etiology of epidermoid cyst is unclear. A suggested theory is that oral epidermoid cyst can be congenital or acquired[6,7]. The congenital type may result from the failure of the surface ectoderm to separate from the underlying neural tube, or the invagination of the surface ectoderm along the embryologic fusion sites[6]. The acquired type is caused by trauma, with implantation of the surface epithelial element into the deeper tissue[6]. There are no clinical or histopathological differences between the congenital and acquired types[7]. In this case, the lesion developed in the upper lip. Since the lips are vulnerable to traumatic injuries, the lesion could be acquired. On the other hand, the cysts could be congenital as the patient was an infant with no history of trauma or surgery. It was difficult to determine whether the epidermoid cyst was congenital or acquired.

Epidermoid cysts have the typical characteristics of benign lesions. This case also presented with the same clinical findings. Depending on the size and location of the mass, the cysts could present with obstructive symptoms such as dyspnea, dysphonia, dysphagia[3]. Moreover, the cyst wall may rupture[8] or get secondarily infected[9]. Normally, secondary infection is unusual, but it can cause life-threatening situations when it occurs[9]. In rare cases, the formation of a sinus tract from the oral cavity to the skin and muscle fusion defects have been reported[10]. There are studies of malignant transformation in long-standing, untreated epidermoid cysts[11,12]. Epidermoid cysts are usually solitary lesions, as in this case. However, multiple masses can be occur in the floor of the mouth[13].

There have been a limited number of cases of epidermoid cysts found in the upper lip. The first case was diagnosed by Kuroyanagi *et al.*[14] in 1973. Koh[15] reported the case of a cyst with a sinus tract extension to the skin. Kim and Hong[16] described a giant epidermoid cyst in a patient wearing a denture. Dogan and Bucak[10], Phukan *et al.*[17], Mahalakshmi *et al.*[18], and recently, Chen *et al.*[19] have also reported epidermoid cysts in the upper lip. All 7 cases showed characteristic

histological findings of typical epidermoid cysts similar to the present case.

It is necessary to make a differential diagnosis with other lesions. In this case, infection was ruled out because of the absence of pain, signs of inflammation, and focus of infection. A neoplastic hypothesis was excluded as the clinical findings were not suggestive of malignancy.

The lip contains adipose tissue, connective tissue, blood vessels, nerves, and salivary glands. Any lesion that originates from these components may occur in the lip. The most common clinical differential diagnosis of a cystic lip mass is mucocele. Considering characteristics of the lesion based on palpation and appearance, the cyst was different from mucocele[20]. Other clinical differential diagnoses of lip masses include mucous retention cyst, sialolith, fibroma, and lipoma[21-23]. Mucous retention cysts usually occur in older adults. Sialoliths may also present as masses in the upper lip. However, sialoliths are usually not cystic[21]. Fibromas and lipomas are benign lesions with similar clinical features to the lesion. Fibromas are the most frequently found soft tissue lesions in the oral cavity and the lips[22]. Lipomas are benign soft tissue tumors composed of adipose tissue with a slightly yellowish, soft and fluctuant swelling[23]. In this case, a provisional diagnosis of fibroma or lipoma was made, as the lesion was soft, movable, and fluctuant with a cystic consistency.

Histopathological examination of the cyst is required to confirm the diagnosis. Histologically, epidermoid cysts are lined with stratified squamous epithelium and usually filled with cheese-like material or keratin[24]. Although a diagnosis can be confirmed by histopathological examination, imaging techniques such as CT or MRI are used as important tools. They precisely delineate the location of the lesions and their relation with adjacent structures[24].

In this case, excisional biopsy was performed under the provisional diagnosis that the lesion was benign. However, it was hard to determine the depth of the lesion because there was no 3D image evaluation during the surgical procedure. The upper lip is the boundary between the oral cavity and the skin. As the lesion can also penetrate the tissues, it would be important to understand the depth of the lesion through preoperative image evaluation. In addition, it is significant to predict possible complications through 3D image of the cysts and obtain patient consent in advance. It would be helpful to assess whether the anatomical structure was damaged by the location or growth of the lesion prior to surgery.

The treatment of choice is surgical excision, using an intra-oral or extraoral approach depending on the location of the lesion[4]. In this case, surgical excision was performed using an intraoral approach by placing a horizontal incision over the lesion. Care had to be taken to avoid postoperative inflammation or recurrence.

Prognosis is good, and a recurrence rate of < 3% has been reported[25]. A 5% rate of malignant transformation of the teratoid variety has been reported[11,12]. In this case, the intraoral wound healed without complications. No signs of infection or recurrence were noted during the 6 months follow up.

IV. Summary

An exceptionally atypical case of epidermoid cyst occurring in the inner mucosa of the upper lip was treated surgically in this study. Although epidermoid cysts are rarely encountered in the oral cavity, there is a possibility of occurrence of the lesions. It requires that clinicians are aware of the lesion and consider it in their differential diagnosis. Pediatric dentists are often the first to recognize oral pathologies. Therefore, a careful evaluation of soft tissue as well as hard tissue should be performed during oral examinations.

전남대학교 치의학전문대학원 소아치과학교실

유표피낭종은 구강 내에서 드물게 보이는 양성병소이며 선천적 혹은 후천적으로 발생할 수 있다. 이 병소는 대개 느리게 자라는 낭종으로, 저작이나 발음을 방해 할 정도로 크기가 커지거나 2차 감염이 발생하기 전까지는 주로 무증상을 보인다. 따라서 진단이 지연되는 경우가 많으며, 신생아나 영유아에서 진단되는 경우는 매우 드문 병소이다. 유표피낭종은 대부분 구강저에서 발생하며 상순에서의 발생은 드물다. 이 증례에서는 29개월 환아의 상순 내측 점막에서 촉진되는 종물을 구강 내 접근법을 이용하여 외과적으로 적출하고, 조직 병리학적으로 유표피 낭종으로 진단하였기에 보고하는 바이다.
